In this paper, the tellurite glasses 76.4TeO₂-12Nb₂O₅-12.6ZnO doped with 3000ppm Tm³⁺ ions were prepared by conventional melt quenching method. The optical properties of the glasses were estimated by measuring UV–Vis-NIR spectroscopy in the range from 200 to 2500 nm and linear refractive indices (n) at different wavelength was estimated. From the absorption edge studies, the value of optical band gap (E_{opt}) was determined. Moreover, the nonlinear refractive index (n_2), third-order nonlinear susceptibility (χ(3)), and nonlinear absorption coefficient, (β), were observed. It is noticed that (n_2), χ(3) and β increase by decreasing the value of optical band gap (E_{opt}). The classical McCumber theory was used to evaluate the emission cross-sections for the 3F₄ → 1H₆ transition at a wavelength of around 2μm. Gain cross-section for the Tm³⁺ laser transition 3F₄ → 1H₆ was obtained. These glasses have the effective emission cross section bandwidth (108 nm) and large stimulated emission cross-section (28.37×10⁻²⁴cm³). Spectroscopic properties indicate that these glasses doped with Tm³⁺ are a promising candidate for optical applications and may be suitable for optical fibre lasers and amplifiers. Furthermore, the structures of these glasses were analyzed by Raman spectroscopy.

(Received February 14, 2018; Accepted April 24, 2018)

Keywords: TeO₂; Linear refractive indices, Emission cross section; Gain.

1. Introduction

Newly, much interest has been played to Tm³⁺ doped glasses due to their optical properties for several applications, such as optical reading, atmospheric sensing, some applications in medical surgery and eye-safe laser radar [1–4]. Most of the investigations on Tm³⁺ ions have been focused on their four metastable multiplets 3F₂, 3H₄, which emit in the NIR region and 3G₄, 1D₂ which emit mainly in the visible region. Especially interesting is the emission at 1.8μm which is attribute to the 3F₄ → 1H₆ transition and the blue emission (1D₂ → 3F₄) which could be used for visible lasers. However, the host material is one of the important issues that need to be considered. Amongst the potential candidates as hosts, tellurite glasses of far several advantages including ease and low production cost in comparison to single crystal counter parts, high chemical stability and a wide transmission range from ultraviolet to mid-infrared (0.35–5.0μm) [5–7]. In comparison to silicate and phosphate glasses, tellurite glasses have lower melting temperature [8,9], a higher refractive index [10], a good infrared transmittance [11] as well as smaller phonon energy that reduces the effect of non-radiative decay and therefore results in higher luminescence quantum efficiencies. Furthermore, the solubility of rare earth oxides is much higher than in SiO₂ glasses [12].

This work presents a study of the optical properties of tellurite glasses doped with 3000ppm. The emission cross sections determined using the McCumber theory. Furthermore, the structure of these glasses was analyzed by Raman spectroscopy.

2. Experimental Procedure

Tellurite glasses with the molar composition 76.4TeO₂- 12Nb₂O₅-12.6ZnO in mol% (TNZ: Tm) was prepared by melt quenching technique from the raw materials TeO₂- Nb₂O₅-ZnO and Tm₂O₃, which all were used as high purity reagents (> 99.99%). The powder was mixed and heated in a platinum crucible in the furnace at 950 °C for 45min. Subsequently, the highly viscous melt was cast to a graphite mould. The quenched glass was annealed at 300 °C for 2 hours, then slowly cooled down to room temperature. The glasses sample was cut and polished to different geometries for spectroscopic studies and optical measurements. The thickness of the studied samples is L =4.51 mm. The density of the glasses was measured using helium pycnometer (AccuPyc1330, Micromeritics GmbH, Germany) with an accuracy of ±0.0001 g/cm³.

The structure of this tellurite glass was studied using a Raman spectrometer (Senterra, Bruker GmbH, Germany) under an excitation of 514 nm. The transmission spectrum was measured using a Fourier transform spectrometer Vector 22 (Bruker GmbH, Germany). The absorption spectrum was recorded at wavelengths in the range of 190–2500nm using UV/Vis/NIR spectrophotometer 3101PC (Shimadzu, Japan) error of about 1%.

3. Results and discussion

3.1. Refractive index and density

Linear refractive indices measured at the wavelengths 436, 480, 546, 589 and 644nm are 3.3701, 3.0939, 2.8511, 2.7497 and 2.6579, respectively (shown in Fig.1). The refractive index is affected by many factors such as the electronic polarizability of the ions which are included in the glasses composition and the optical basicity of the glasses.

![Fig. 1. Variation of refractive index as a function of wavelength for the TNZ doped with Tm³⁺ ions.](image)

On the other hand, the linear refractive index depends on the wavelength and it is given by the wimple equation [13].

\[
\frac{1}{n^2(E)-1} = \frac{E_s}{E_d} - \frac{E_s^2}{E_d E_d},
\]

where E is the light energy (= hν), E_s is called Sellmeier gap which is usually considered as the energy separation between the centers of both the conduction and the valence bands energy and E_d is the dispersion energy or the average oscillator strength. This latest measures the average strength of interband optical transitions. From the linear regression of the curve 1/(n²–1) vs. E² (see Fig. 2), values for E_d and E_s of 18.34 and 3.88eV, are respectively obtained.
The third order nonlinear susceptibility, $\chi^{(3)}$, of glasses according to the theory of Lines [14,15] and Kim et al. [16] can be calculated as follows:

$$\chi^3 = 25 \times 10^{-13} \cdot \left(\frac{1}{3} \cdot n^2 + 2\right)^3 \cdot \frac{d^2}{n_e [\epsilon_2 - \epsilon_2] \cdot \epsilon_2^4},$$

where: $f$ is the local field enhancement factor and $d$ is the bond length between cation and anion, in angstrom. The nonlinear refractive indices $n_2$ is related to $\chi^3$ by the following relation: $\chi^3$ (esu) = $n_2 / 3\pi$. $n_2$ (esu). The $n_2$ values and $\chi^{(3)}$ of 92.9 $\times$ 10$^{-15}$ (cm$^2$/w) and 143.6 $\times$ 10$^{-13}$ (esu), respectively. The two photon non-linear absorption coefficient (TPA), $\beta$ can be calculated using the following expression: $\beta = KE_p^{1/2} F / n^2 E_g^3$, where $F$ is the function which represents the dispersion of $\beta$ with respect to the incident photon energy $h\nu$. The photon energy $h\nu$ range is selected at wavelength satisfying the two-photon absorption TPA condition: $E_g/2 < h\nu < E_{opt}$. If the glasses have high nonlinear absorption coefficient this leads to promising properties for nonlinear optical devices such as power limiters, real time holography, ultrafast optical switches, self focusing and white light continuum generation. In the present work, the value of $\beta$ is 4.38 cm GW$^{-1}$. In the glasses with the compositions 76TeO$_2$-20Nb$_2$O$_5$-4BaO and 60TeO$_2$-10Bi$_2$O$_3$-30WO$_3$, the value of, $\beta$, was reported as 1.72 and 0.565, respectively. By using femto-second Z-scan method at 800 nm the value of $\beta$ for TeO$_2$-Bi$_2$O$_3$-BaO and TeO$_2$-Bi$_2$O$_3$-TiO$_2$, glasses were obtained; they were in range from 1.037 to 4.141 cG/W. Thus the present glasses should have promising properties for the above mentioned applications.

The optical absorption edge is an important parameter for describing solid-state materials and it is interpreted in terms of direct or indirect transitions across an optical bandgap. The absorption coefficient, $\alpha(\omega)$, is given by [23]: $\alpha(\omega) = A (h\omega - E_{opt})^{\gamma}$, where $A(\omega)$ is the absorption coefficient, $A$ is constant, $E_{opt}$ is the optical band edge and $h\omega$ is the photon energy of the incident radiation. The exponent, $r$, is taken different value which depend on the mechanism of the interband transition [24]. $E_{opt}$ is estimated by extrapolating from the linear regions of the curves $(a h\nu)^{1/2}$ vs. $h\nu$ as shown in Fig. 3. The value of optical energy gap equals to 2.7eV. This comparatively high value of the optical energy gap provides the possibility that these glasses may be suitable for optical device components.
The density of TNZ:Tm glasses is determined to be $\rho = 5.381 \pm 0.0026$ g/cm$^3$ that can be used to calculate the concentration of Tm$^{3+}$ ions by the relation: $N = [\text{RE mol\%}] \frac{\rho}{M} 2A_{\nu}$, Where [RE mol\%] is the molar percentage of rare-earth oxide based on the molar mass of the glasses composition, $M$ is the molecular weight of the TNZ:Tm glasses. The concentration of Tm$^{3+}$ in the doped TNZ glass is $N = 1.176581 \times 10^{20}$ ions/cm$^3$.

3.2. Absorption spectroscopy, emission cross section and gain coefficient

The Judd–Ofelt (JO) theory is widely used for predicting the possibility of laser action, as well as of optical amplification, through an analysis of the forced electric dipole transitions within the 4f$^n$ configuration of rare-earth ions in different isotropic lattices (crystalline and amorphous) [25-27]. The absorption spectrum of 3000ppm Tm$_2$O$_3$ doped TNZ glasses, which is obtained at room temperature over a spectral range of 200–2500nm is shown in Fig. 4. The absorption spectrum is characterized by five bands centred at 1726, 1214, 794, 686 and 468 nm, corresponding to the absorptions starting from the ground state $^3$H$_6$ to the excited states $^3$F$_4$, $^3$H$_5$, $^3$H$_4$, $^3$F$_3$ and $^1$G$_4$, respectively. The transitions to energy levels higher than $^1$G$_4$ are not observed because of the intrinsic conduction band absorption of the host glass.

The absorption cross-sections of the Tm$^{3+}$ ion for the $^3$F$_4$→$^3$H$_6$ transition can be calculated as follows: $\sigma_a(\lambda) = \frac{2.303 \cdot OD(\lambda)}{NL}$, Where OD ($\lambda$) = log ($I_0/I$) is the optical density of the experimental absorption spectrum, $L$ is the thickness of the sample and $N$ is the concentration of respective rare-earth ions.

The stimulated emission cross-section $\sigma_e(\lambda)$ of Tm$^{3+}$ for the $^3$F$_4$→$^3$H$_6$ transition can be deduced from their corresponding ground state absorption cross-section $\sigma_a(\lambda)$ using the following
equation [28]:

\[
\sigma_e(\lambda) = \sigma_a(\lambda) \frac{Z_l}{Z_u} \exp \left( \frac{-E_{Z_l} - h\nu \hbar}{K_b T} \right)
\]

Where \( Z_l \) and \( Z_u \) are the partition functions for the lower and the upper levels involved in the considered optical transition, \( T \) is the temperature (in this case the room temperature), and \( E_{Z_l} \) is the zero line energy for the transition between the lower Stark sublevels of the emitting multiplets and the lower Stark sublevels of the receiving multiplets.

Fig. 5 shows the calculated absorption and emission cross sections for the present glasses. The peak of the stimulated emission cross-section (\( \sigma_e^{peak} \)) is about 28.37 × 10^{-21} cm^2 respectively. The highest value of (\( \sigma_e^{peak} \)) for the emission cross-section is related to the larger value of the line strength of the \( ^3F_4 \rightarrow ^3H_6 \) and may be due to the higher refractive index of the glasses matrix.

The comparison value of the emission cross of the Tm^{3+} transition \(^3H_6 \leftrightarrow ^3F_4\) in various glass hosts at around 2 µm of the TNZ:Tm glasses (28.37 × 10^{-21} cm^2) is larger than those of other glasses (TNZ: Sm [29], Gallate [30], Germanate [31], Bismuthate [32], PZC: Er [33] and PZS: Er [33]) (1.09 × 10^{-20}, 3.8 × 10^{-21}, 7.7 × 10^{-21}, 6.7 × 10^{-21}, 0.47 × 10^{-20} and 0.39 × 10^{-20} cm^2). For laser glasses, it is generally desirable for the emission crosssection to be as large as possible in order to provide high gain [34]. It indicates that the doped glasses TNZ:Tm is a promising candidate for laser glass at 2 µm and 1952 nm. The FWHM of the emission peak is also a critical parameter that is used to evaluate the gain bandwidth properties of the optical amplifiers is 110 nm respectively.

Due to the large overlap of the absorption and emission spectrum of Tm^{3+} ions at 2 µm, reabsorption will occur and cause the fluorescence spectrum deformed. Thus, due to the asymmetric profile of the emission line, it is more reasonable to calculate an effective line width, instead of the FWHM. The effective line width (\( \Delta \lambda \)) can be expressed as

\[
\Delta \lambda = \frac{\int \sigma_e(\lambda) d\lambda}{\sigma_e^{peak}}
\]

The optical gain coefficient is an important factor for evaluating the performance of laser media. The light field intensity derived from the light field power by the simplified relationship

\[
I(Z) = \frac{P(Z)}{A}
\]

where \( P(Z) \) is pump power at the position \( Z \) and \( A \) is an effective cross sectional area of the core. The propagation equation for the pump and signal field power \( P(Z) \) in a given direction are thus [36,34]:

\[
\frac{dP(Z)}{dz} = [\sigma_e N_2(Z) - [\sigma_a N_1(Z)] P(Z)
\]

Where \( N \) is total population volume-density and defined as \( N = N_1 + N_2 \). \( N_1 \) and \( N_2 \) represent the population volume- densities of upper and lower levels, respectively. From the absorption and emission cross sections for the transitions between two laser operating levels, the optical gain cross section \( \sigma_{gain} \) lead to an estimation of the probable operating laser wavelength. If \( P \) is the population inversion rate for \( ^3F_4 \rightarrow ^3H_6 \), Tm^{3+} laser transition, the gain cross section can be calculated using the following relation:

\[
\sigma_{gain} = P \sigma_{em}(\lambda) - (1 - P) \sigma_{abs}(\lambda), \text{ where } \sigma_{em} \text{ and } \sigma_{abs} \text{ are emission and absorption cross sections,}
\]
respectively. The wavelength dependence of the gain cross section was calculated for different values of population inversion \( P \) (\( P = 0, 0.1, 0.2, \ldots , 1 \)) and are shown in fig. 6.

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{gain_coefficient.png}
\caption{The gain coefficient of the transition \( ^{3}F_{4} \rightarrow ^{1}H_{6} \) for TNZ: Tm glass.}
\end{figure}

In the case of total inversion at 1952nm, again coefficient of 28.5cm\(^{-1}\) is obtained for TNZ doped with 3000ppm Tm\(_{2}\)O\(_{3}\) ions. But, as it is known for such laser systems, the inversion coefficient fraction is more likely close to 0.4 which leads to the gain coefficient values of 3.5 \times 10\(^{-21}\)cm\(^{-1}\) at 1970nm. Laser experiments for these emissions are expected to find light amplification in the future.

3.3. Raman Spectra

Fig. 7 shows the spectrum of TNZ: Tm is deconvoluted using Gaussian fitting to four peaks at about 409, 516, 686 and 800cm\(^{-1}\) which are labeled as A, B, C and D bands respectively. It show that abroad Raman band(A) at 409cm\(^{-1}\) that are assigned to the symmetrical stretching or bending vibrations of Te–O–Te linkages which are formed by corner-sharing of (TeO\(_{4}\)), (TeO\(_{3+1}\)) polyhedral andTeO\(_{3}\) units [37–39]. The peak (B) is ascribed to the axial symmetrical stretching modes of (Te\(_{ax}\)–O)\(_{s}\) of TeO\(_{4}\) tetrahedra [40–43]. The band (C) is assigned to the (Te\(_{eq}\)–O)\(_{s}\) and (Te\(_{eq}\)–O)\(_{as}\) vibration modes of TeO\(_{3+1}\) polyhedra orTeO\(_{3}\) trigonal bipyramids units [44, 45] and peak (D) attributed to the stretching vibrations of Nb – O bonds in NbO\(_{6}\) octahedra [45].

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{raman_spectra.png}
\caption{Deconvoluted Raman spectra of TNZ: Tm glass.}
\end{figure}

4. Conclusion

The optical properties of the glasses were estimated by measuring UV–Vis-NIR spectroscopy. Indirect optical band gap energy value is 2.7eV. The present glasses have the high absorption intensities, emission cross-sections. The optical gain coefficient of the population inversion of the \( ^{3}F_{4} \) level (3.5 \times 10\(^{-21}\)cm\(^{-1}\)) and an effective bandwidth of 108nm for glasses has
been evaluated. The spectroscopic data obtained that the TNZ:Tm glasses can be used as a candidate for optical devices around at 2μm.
